Overview

This project has been implemented as part of the Data Science: Capstone project in edX. This report has all details related to the project and the thought process behind the final objective of a recommender model.

We start with a basic introduction and objective. This is followed by basic data analysis and cleaning for preparation. An exploratory data analysis is carried out in order to develop multiple machine learning models that can predict movie ratings and then finalize a model. The report ends with an explanation of the results and a conclusion.

Introduction

Recommendation systems use ratings that users have given to items to make specific recommendations. Companies that sell many products to many customers and permit these customers to rate their products, like Amazon, are able to collect massive datasets that can be used to predict what rating a particular user will give to a specific item. Items for which a high rating is predicted for a given user are then recommended to that user.

The same could be done for other items, as movies for instance in our case. Recommendation systems are one of the most used models in machine learning algorithms. In fact the success of Netflix is said to be based on its strong recommendation system. The Netflix prize (open competition for the best collaborative filtering algorithm to predict user ratings for films, based on previous ratings without any other information about the users or films), in fact, represent the high importance of algorithm for products recommendation system.

For this project we will focus on create a movie recommendation system using the 10M version of MovieLens dataset, collected by GroupLens Research.

Aim of the project

The aim in this project is to train a machine learning algorithm that predicts user ratings (from 0.5 to 5 stars) using the inputs of a provided subset.

The value used to evaluate algorithm performance is the Root Mean Square Error, or RMSE. RMSE is one of the most used measure of the differences between values predicted by a model and the values observed. RMSE is a measure of accuracy, to compare forecasting errors of different models for a particular dataset, a lower RMSE is better than a higher one. The effect of each error on RMSE is proportional to the size of the squared error; thus larger errors have a disproportionately large effect on RMSE. Consequently, RMSE is sensitive to outliers. The evaluation criteria for this algorithm is a RMSE expected to be lower than 0.8775.

The best resulting model will be used to predict the movie ratings.

Dataset

For this recommender system, we use a version of the movielens dataset. This is a small subset of a much larger dataset with millions of ratings. We will use the 10M version of the complete MovieLens dataset to make the computation a little easier.

The MovieLens dataset is automatically downloaded from:

- [MovieLens 10M dataset] https://grouplens.org/datasets/movielens/10m/
- [MovieLens 10M dataset zip file] http://files.grouplens.org/datasets/movielens/ml-10m.zip

MovieLens 10M movie ratings is a stable benchmark dataset. It has 10 million ratings and 100,000 tag applications applied to 10,000 movies by 72,000 users.

Load Dataset

[1] "/var/folders/yc/crffhmc5649blbjdw95z94100000gn/T//Rtmp02u10F/file9959533feb56"

In order to predict in the most possible accurate way the movie rating of the users that haven't seen the movie yet, the MovieLens dataset will be split into 2 subsets: • edx: a training subset to train the algorithm • validation: a subset to test the movie ratings

```
# Validation set will be 10% of MovieLens data

set.seed(1) # if using R 3.6.0: set.seed(1, sample.kind = "Rounding")
test_index <- createDataPartition(y = movielens$rating, times = 1, p = 0.1, list = FALSE)
edx <- movielens[-test_index,]
temp <- movielens[test_index,]

# Make sure userId and movieId in validation set are also in edx set

validation <- temp %>%
    semi_join(edx, by = "movieId") %>%
    semi_join(edx, by = "userId")

# Add rows removed from validation set back into edx set

removed <- anti_join(temp, validation)
edx <- rbind(edx, removed)

#rm(dl, ratings, movies, test_index, temp, movielens, removed)</pre>
```

Data exploration and analysis

```

Rating Distribution

The chart shows that whole-number ratings are more common that 0.5 ratings. This also shows that users have a preference to rate movies rather higher than lower as shown by the distribution of ratings 4 is the most common rating, followed by 3 and 5. 0.5 is the least common rating.

To make further analysis on the rating distribution, we will validate and update the edx dataset

Continuing with the analysis

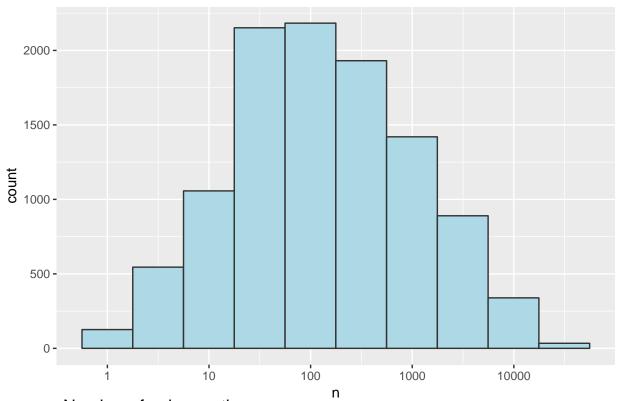

Ratings by year

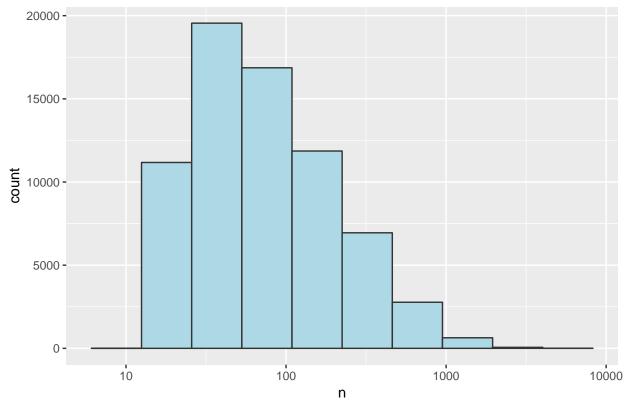

We observe that more recent movies get more user ratings. Movies earlier than 1950 get few ratings, whereas newer movies, especially in the 90s get far more ratings.

Movie Rating by Age

This follows our earlier observation and also shows higher ratings for older movies up to about ~ 80 years after which the ratings decline.

To further understand what affects the ratings, we will try to correlate all the available parameters

| ## | | rating | ${\tt movieId}$ | userId | year | age_of_movie | premiered | n | avg_m_r |
|----|---|--------|-----------------|--------|------|--------------|-----------|-------|----------|
| ## | 1 | 5 | 122 | 1 | 1992 | 27 | 1992 | 2178 | 2.858586 |

| ## | 5 | 5 | 329 | 1 | 1994 | 25 | 1994 | 14550 | 3.337457 |
| ## | 6 | 5 | 355 | 1 | 1994 | 25 | 1994 | 4831 | 2.487787 |

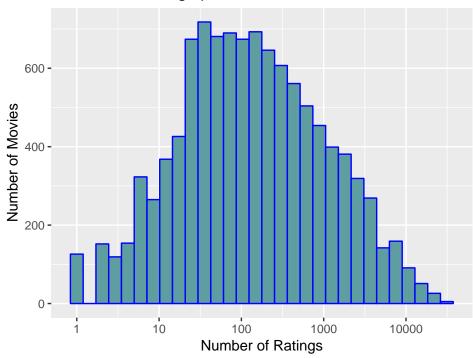

We notice that some movies have been rated much often than others, while some have very few ratings and sometimes even only one rating. This will be important for our model as very low rating numbers might results in untrustworthy estimate for our predictions. Almost 125 movies have been rated only once.

We also notice that some movies have been rated a lot more often than others, while some have very few ratings and sometimes even one rating

```
edx %>%
count(movieId) %>%
ggplot(aes(n)) +
geom_histogram(bins = 30, color = "blue", fill = "cadetblue") +
scale_x_log10() +
xlab("Number of Ratings") +
  ylab("Number of Movies") +
ggtitle("Number of Ratings per Movie")
```

Number of Ratings per Movie

We notice that these movies have only one rating, making future rating prediction difficult.

```
edx %>%
  group_by(movieId) %>%
  summarize(count = n()) %>%
  filter(count == 1) %>%
  left_join(edx, by = "movieId") %>%
  group_by(title) %>%
  summarize(rating = rating, n_rating = count) %>%
  slice(1:20) %>%
  knitr::kable()
```

| title | rating | n_rating |

One can observe that the majority of users have rated between 30 and 100 movies. So, a user penalty term needs to be included later in our models.

```
# Plot number of ratings given by users
edx %>%
count(userId) %>%
ggplot(aes(n)) +
geom_histogram(bins = 30, color = "blue", fill = "cadetblue") +
scale_x_log10() +
xlab("Number of Ratings") +
ylab("Number of Users") +
ggtitle("Number of Ratings given by Users")
```

```
## Warning: Computation failed in `stat_bin()`:
## `binwidth` must be positive
```

Number of Ratings given by Users

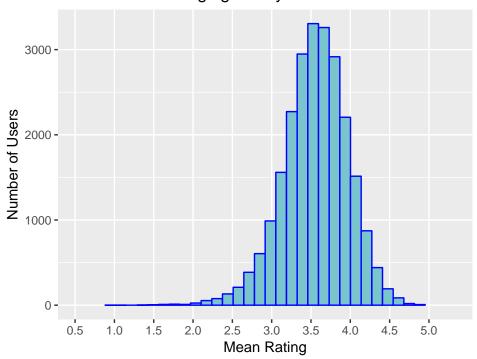

Number of Users

Number of Ratings

Furthermore, users differ vastly in how critical they are with their ratings. Some users tend to give much lower star ratings and some users tend to give higher star ratings than average. The visualization below includes only users that have rated at least 100 movies.

```
edx %>%
  group_by(userId) %>%
  filter(n() >= 100) %>%
  summarize(b_u = mean(rating)) %>%
  ggplot(aes(b_u)) +
  geom_histogram(bins = 30, color = "blue",fill="cadetblue3") +
  xlab("Mean Rating") +
  ylab("Number of Users") +
  ggtitle("Mean Movie Ratings given by Users") +
  scale_x_discrete(limits = c(seq(0.5,5,0.5)))
```

Mean Movie Ratings given by Users

Modelling Approach

The loss-function, that computes the RMSE is defined as follows:

$$RMSE = \sqrt{\frac{1}{N} \sum_{u,i} (\hat{y}_{u,i} - y_{u,i})^2}$$

with N being the number of user/movie combinations and the sum occurring over all these combinations. The RMSE is our measure of model accuracy.

The written function to compute the RMSE for vectors of ratings and their corresponding predictions is:

```
RMSE <- function(true_ratings, predicted_ratings){
    sqrt(mean((true_ratings - predicted_ratings)^2))
}</pre>
```

1. Average Movie Rating Model

The first model predicts the same rating for all movies, so we compute the dataset's mean rating. The expected rating of the underlying data set is between 3 and 4. We start by building the simplest possible recommender system by predicting the same rating for all movies regardless of user who give it. A model based approach assumes the same rating for all movie with all differences explained by random variation:

$$Y_{u,i} = \mu + \epsilon_{u,i}$$

with $\epsilon_{u,i}$ independent error sample from the same distribution centered at 0 and μ the "true" rating for all movies. This very simple model makes the assumption that all differences in movie ratings are explained by random variation alone. The estimate that minimizes the RMSE is the least square estimate of $Y_{u,i}$, in this case, is the average of all ratings: The expected rating of the underlying data set is between 3 and 4.

```
mu <- mean(edx$rating)
mu</pre>
```

[1] 3.512465

If we predict all unknown ratings with μ or mu, we obtain the first RMSE:

```
model_1_rmse <- RMSE(validation$rating, mu)
model_1_rmse</pre>
```

[1] 1.061202

Here, we represent results table with the first RMSE:

| method | RMSE |
|----------------------------|----------|
| Average Movie Rating Model | 1.061202 |

This give us our baseline RMSE to compare with next modelling approaches.

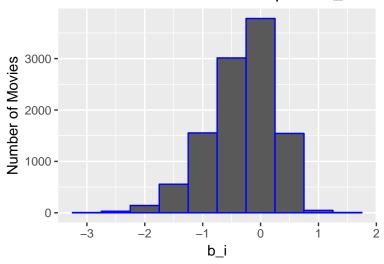

In order to do better than simply predicting the average rating, one can incorporate some of insights gained during the exploratory data analysis.

2. Movie Effect Model

To improve above model one can focus on the fact that some movies are just generally rated higher than others. Higher ratings are mostly linked to popular movies among users and the opposite is true for unpopular movies. We compute the estimated deviation of each movies' mean rating from the total mean of all movies μ . The resulting variable is called "b" (as bias) for each movie "i" b_i , that represents average ranking for movie i:

$$Y_{u,i} = \mu + b_i + \epsilon_{u,i}$$

Number of Movies with Computed b_i

The histogram is left skewed, implying that more movies have negative effects This is called the penalty term movie effect.

Our prediction can improve once prediction is done using this model.

| method | RMSE |
|----------------------------|-----------|
| Average Movie Rating Model | 1.0612018 |
| Movie Effect Model | 0.9439087 |

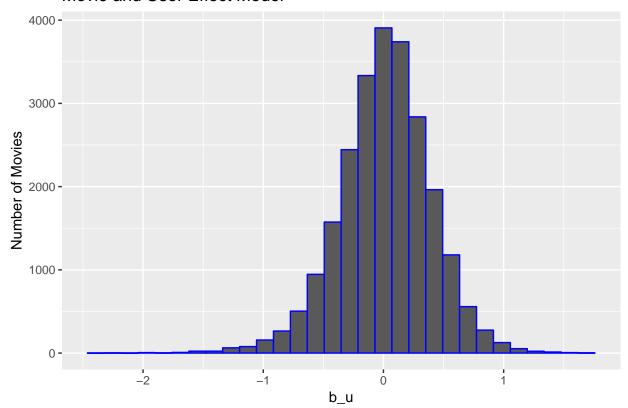

So we have predicted movie rating based on the fact that movies are rated differently by adding the computed b_i to μ . If an individual movie is on average rated worse that the average rating of all movies μ , we predict that it will rated lower that μ by b_i , the difference of the individual movie average from the total average.

We can see an improvement but this model does not consider the individual user rating effect.

3. Movie and User Effect Model

The average rating for user μ , for those that have rated over 100 movies, said penalty term user effect. In fact users affect the ratings positively or negatively.

Movie and User Effect Model

There is substantial variability across users as well: some users are very cranky and others love every movie. This implies that further improvement to the model may be:

$$Y_{u,i} = \mu + b_i + b_u + \epsilon_{u,i}$$

where b_u is a user-specific effect. If a cranky user (negative b_u rates a great movie (positive b_i), the effects counter each other and we may be able to correctly predict that this user gave this great movie a 3 rather than a 5.

An approximation can be computed by μ and b_i , and estimating b_u , as the average of

$$Y_{u,i} - \mu - b_i$$

```
user_avgs <- edx %>%
  left_join(movie_avgs, by='movieId') %>%
  group_by(userId) %>%
  summarize(b_u = mean(rating - mu - b_i))
```

Construct predictors can improve RMSE.

| method | RMSE |
|-----------------------------|-----------|
| Average Movie Rating Model | 1.0612018 |
| Movie Effect Model | 0.9439087 |
| Movie and User Effect Model | 0.8653488 |

Our rating predictions further reduced the RMSE, But still, mistakes were made on our first model (using only movies). The supposed "best" and "worst" movies were rated by few users, in most cases just one user. These movies were mostly obscure ones. This is because with a few users, more uncertainty is created. Therefore larger estimates of b_i , negative or positive, are more likely.

Until now, the computed standard error and constructed confidence intervals account for different levels of uncertainty. The concept of regularization permits to penalize large estimates that come from small sample sizes. The general idea is to add a penalty for large values of b_i to the sum of squares equation that we minimize. So having many large b_i , make it harder to minimize. Regularization is a method used to reduce the effect of overfitting.

4. Regularized Movie and User Effect Model

So estimates of b_i and b_u are caused by movies with very few ratings and in some users that only rated a very small number of movies. Hence this can strongly influence the prediction. The use of the regularization permits to penalize these aspects. We should find the value of lambda (that is a tuning parameter) that will minimize the RMSE. This shrinks the b_i and b_u in case of small number of ratings.

```
lambdas <- seq(0, 10, 0.25)

model_4_rmse <- sapply(lambdas, function(1){
    mu <- mean(edx$rating)

b_i <- edx %>%
    group_by(movieId) %>%
```

```
summarize(b_i = sum(rating - mu)/(n()+1))

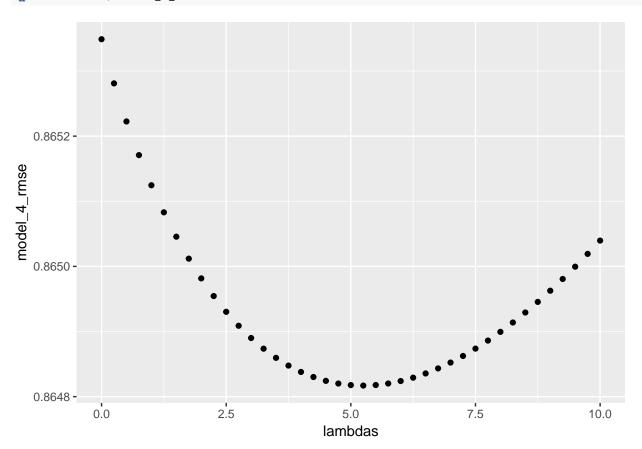

b_u <- edx %>%
  left_join(b_i, by="movieId") %>%
  group_by(userId) %>%
  summarize(b_u = sum(rating - b_i - mu)/(n()+1))

predicted_ratings <-
  validation %>%
  left_join(b_i, by = "movieId") %>%
  left_join(b_u, by = "userId") %>%
  mutate(pred = mu + b_i + b_u) %>%
  pull(pred)

return(RMSE(predicted_ratings, validation$rating))
})
```

We plot RMSE vs Lambdas to select the optimal lambda

qplot(lambdas, model_4_rmse)

For the full model, the optimal lambda is:

```
lambda <- lambdas[which.min(model_4_rmse)]
lambda</pre>
```

[1] 5.25

For the full model, the optimal lambda is: 5.25

The new results will be:

| method | RMSE |
|---|-----------|
| Average Movie Rating Model | 1.0612018 |
| Movie Effect Model | 0.9439087 |
| Movie and User Effect Model | 0.8653488 |
| Regularized Movie and User Effect Model | 0.8648170 |

Results

The RMSE values of all the represented models are the following:

```
rmse_results %>% knitr::kable()
```

| method | RMSE |
|---|-----------|
| Average Movie Rating Model | 1.0612018 |
| Movie Effect Model | 0.9439087 |
| Movie and User Effect Model | 0.8653488 |
| Regularized Movie and User Effect Model | 0.8648170 |

The lowest identified value of RMSE is 0.8648170.

Discussion

It can be confirmed that the final model for the project is the following:

$$Y_{u,i} = \mu + b_i + b_u + \epsilon_{u,i}$$

This model will work well if the average user doesn't rate a particularly good/popular movie with a large positive b_i , by disliking a particular movie.

Conclusion

A machine learning model has been successfully built to predict movie ratings with MovieLens dataset. The optimal model (Regularized Model) characterised by the lowest RMSE value (0.8648170) is thus the optimal selection. This is lower than the initial evaluation criterion (0.8775) given by the goal of the present project.
